String Localization and Message Dictionaries

This article explains:

- How InterSystems products support [string localization](#)
- The structure of a [message dictionary](#)
- The structure of an [XML message file](#)
- How to import, export, and otherwise [manage a message dictionary](#)

1 Overview

When you *localize* the text for an application, you create an inventory of text strings in one language, then establish a convention for substituting translated versions of these messages in another language when the application locale is different.

InterSystems products support the following process for localizing strings:

1. Developers include localizable strings within their code (within a REST application or a Business Intelligence model).

The mechanisms for this vary, but the most common mechanism is the `$$$TEXT` macro. In the place of a hardcoded literal string, the developer includes an instance of the `$$$TEXT` macro, providing values for the macro arguments as follows:

- The default string
- The domain to which this string belongs (localization is easier to manage when the strings are grouped into domains)
- The language code of the default string

For example, instead of this:

```
write "Hello world"
```

The developer includes this:

```
write $$$TEXT("Hello world", "sampledomain", "en-us")
```

2. When the code is compiled, the compiler generates entries in the message dictionary for each unique instance of the `$$$TEXT` macro.

The message dictionary is a global and so can be easily viewed (for example) in the Management Portal. There are class methods to help with common tasks.

3. When development is complete, release engineers export the message dictionary for that domain or for all domains.

The result is one or more XML message files that contain the text strings in the original language.

4. Release engineers send these files to translators, requesting translated versions.
5. Translators work with the XML message file using any XML authoring tool they prefer. Essentially they translate text from the original language to a new language, without changing the surrounding XML.

6. Translators return a new XML message file that has the same structure and that:
 - Identifies a new [RFC1766](#) value for the *language* attribute of the <MsgFile> element.
 - Contains translated text in the identified language.
7. Release engineers import the translated XML message files into the same namespace from which the original was exported.

Translated and original texts coexist in the message dictionary.
8. At runtime, the application chooses which text to display based on the browser default language.

For details on steps 1 and 2, see the following chapters:

- “[Localizing a REST Service](#)” in the chapter “[Creating REST Services](#)” in *Creating REST Services*
- “[Performing Localization](#)” in the *Business Intelligence Implementation Guide*

The remainder of this article discusses managing the message dictionary.

2 Message Dictionaries

A message dictionary is a global that contains text strings organized by domain name, language name, and message ID:

- The *text* of each message is a string of up to 32K characters. The string may be longer if the database has long strings enabled, but the default maximum is 32K. A message may consist solely of text, or it may also contain one or more parameters specified by %1, %2, etc. You can replace these parameters with text (such as a file name within an error message) when the application page needs to display the message.
- A *domain* name is any arbitrary string. It identifies a group of related text items, such as all messages for a specific application or page. If you assign a domain to a set of messages, you can later perform a particular operation on all messages with the same domain.

A domain name is case-sensitive and may contain upper- and lowercase characters. If a domain name begins with %, InterSystems considers all of the messages in that domain to be system messages that are visible in all namespaces. Otherwise, when you create a message it is visible only in the namespace in which it is defined.

- A *language* name is an all-lowercase language tag that conforms to [RFC1766](#). It consists of one or more parts: a primary language tag (such as en or ja) optionally followed by a hyphen (-) and a secondary language tag (en-gb or ja-jp).
- A *message ID* is any arbitrary string; it uniquely identifies a message. The message ID only needs to be unique within a domain. You may assign a message ID or allow the compiler to assign one, depending on the conventions you use to create the message. A message ID is case-sensitive and may contain upper- and lowercase characters.

2.1 Message Dictionary Storage

Each user-defined namespace stores its message dictionary in a subscripted global called `^IRIS.Msg`. The order of subscripts in `^IRIS.Msg` is domain, language, and message ID.

To view `^IRIS.Msg` for a namespace:

1. Start the Management Portal.
2. Switch to the namespace of interest.
3. Click **System Explorer** > **Globals**.

- In the `IRIS.Msg` row, click **View**.

For example:

```
^IRIS.Msg("mydomain")="en"
^IRIS.Msg("mydomain","en",338288369)="sample string"
^IRIS.Msg("mydomain","en",3486914925)="another sample string"
```

3 XML Message Files

An *XML message file* is an export of message dictionary. This is also the required format for any messages that you wish to import. (For export and import instructions, see the section “[Managing a Message Dictionary](#).”)

Whenever possible, XML message files should use UTF-8 encoding. However, in certain cases a developer or translator might use local platform encodings, such as `shift-jis`, for ease of editing the XML message file. Whatever encoding is used for the XML file, it must be supported by the locale for the application, and it must be able to express the messages for the language.

An XML message file may contain messages for one language and multiple domains.

3.1 <MsgFile> Element

The `<MsgFile>` element is the top-level container for the XML message file, and there is only one `<MsgFile>` element per file.

The `<MsgFile>` element has one required attribute, *Language*. The value of the `<MsgFile>` *Language* attribute is an all-lowercase [RFC1766](#) code that identifies the language for the file. It consists of one or more parts: a primary language tag (such as `en` or `ja`) optionally followed by a hyphen (-) and a secondary language tag (`en-gb` or `ja-jp`).

In the following example, this language is `"en"` (English).

```
<?xml version="1.0" encoding="utf-8" ?>
<MsgFile Language="en">
  <MsgDomain Domain="sample">
    <Message Id="source">Source</Message>
    <Message Id="menu">Samples Menu</Message>
  </MsgDomain>
</MsgFile>
```

`<MsgFile>` must contain at least one `<MsgDomain>` element. It may contain more than one `<MsgDomain>`.

3.2 <MsgDomain> Element

The `<MsgDomain>` element has one required attribute, *Domain*. The value of the `<MsgDomain>` *Domain* attribute is one of the domain names that you are using to organize the messages in your application.

Any `<MsgDomain>` element may contain zero or more `<Message>` elements.

3.3 <Message> Element

The `<Message>` element has one required attribute, *Id*. The value of the `<Message>` *Id* attribute is one of the message ID strings that you are using to organize the messages in your application.

Any `<Message>` element may contain a text string. The string may consist of any of the following items, separately or in combination:

- Simple text, as permitted by the file format

- Substitution arguments %1, %2, %3, or %4
- HTML formatting
- A string expression in ObjectScript format

The following example uses %1, %2, the HTML tag for bold formatting, and the ObjectScript string convention that two successive double quote characters indicate a single double quote:

```
<Message>
  The session $Username="&lt;b&gt;%1&lt;/b&gt;" $Roles="&lt;b>%2&lt;/b&gt;"
</Message>
```

4 Managing a Message Dictionary

This section summarizes the %Library.MessageDictionary methods that are most commonly used when working with a message dictionary. You can use these methods to:

- [Import messages](#) from an XML message file
- [Export messages](#) to an XML message file
- [Delete messages](#) from a message dictionary
- [List messages](#) in a message dictionary

4.1 Importing an XML Message File

To import an XML message file, open the Terminal and do the following:

1. Change to the namespace where you are developing the application:

```
ZN "myNamespace"
```

2. Run the import command. By default, each language is in a separate XML message file, with the locale name at the end of the filename. Thus:

- You can import only those messages in a particular language:

```
SET file="C:\myLocation\Messages_ja-jp.xml"
DO ##class(%Library.MessageDictionary).Import(file)
```

- Or, import several languages for the same application:

```
SET myFiles="C:\myLocation"
DO ##class(%Library.MessageDictionary).ImportDir(myFiles,"d")
```

3. Examine the `^IRIS.Msg` global in the same namespace to see the result.

The following topics summarize both import methods.

4.1.1 Importing a Specific XML Message File

The %Library.MessageDictionary class method **Import()** has the following signature:

```
classmethod Import(filepath As %String, flag As %String = "") returns %Status
```

Argument	Description
<i>filepath</i>	Import the XML message file specified by <i>filepath</i> . Make sure that only XML message files are in the directory as other XML files generate errors.
<i>flag</i>	(Optional) If provided, the <i>d</i> flag (display) indicates that the Terminal console will display confirmation messages as files are imported. Otherwise, there is no confirmation.

4.1.2 Importing All the XML Message Files in a Directory

The `%Library.MessageDictionary` class method **ImportDir()** has the following signature:

```
classmethod ImportDir(directory As %String, flag As %String = "") returns %Status
```

Argument	Description
<i>directory</i>	Import all of the XML message files in the specified directory.
<i>flag</i>	(Optional) If provided, the <i>d</i> flag (display) indicates that the Terminal console will display confirmation messages as files are imported. Otherwise, there is no confirmation.

4.2 Exporting an XML Message File

To export portions of a message dictionary to an XML message file, do the following within the Terminal:

1. Change to the namespace where you are developing the application:

```
ZN "myNamespace"
```

2. Identify the output file and its location:

```
SET file="C:\myLocation\Messages.xml"
```

3. Run the export command:

- It may be practical to export only those messages in a particular domain:

```
DO ##class(%Library.MessageDictionary).ExportDomainList(file, "myDomain")
```

- Or, to export all the messages in the namespace:

```
DO ##class(%Library.MessageDictionary).Export(file)
```

The following topics summarize both export methods.

4.2.1 Exporting Specific Domains in One Language

The `%Library.MessageDictionary` class method **ExportDomainList()** has the following signature:

```
classmethod ExportDomainList(file As %String, domainList As %String, language As %String) returns %Status
```

Argument	Description
<i>file</i>	(Required) A template for the output filename in this format: <i>filepath.ext</i> The actual output file name appends the <i>language</i> value to the <i>filepath</i> with an extension of <i>ext</i> .
<i>domainList</i>	(Optional) A comma-separated list of domains to be exported.
<i>language</i>	(Optional) Only the specified <i>language</i> is exported. The value must be an all-lowercase RFC1766 code. If not provided, the value defaults to the system default language, a value that is stored in the special variable <code>\$\$\$DefaultLanguage</code> .

4.2.2 Exporting All Domains in Specific Languages

The `%Library.MessageDictionary` class method **Export()** has the following signature:

```
classmethod Export(file As %String, languages As %String = "", flag As %String = "") returns %Status
```

Argument	Description
<i>file</i>	(Required) A template for the output filename in this format: <i>filepath.ext</i> The name of the output file is <i>filepathlanguage-code.ext</i> For example, if <i>file</i> is <code>c:/temp/mylang_.txt</code> and <i>languages</i> includes the language code <code>ja-jp</code> , then one of the output files is named <code>c:/temp/mylang_ja-jp.txt</code>
<i>languages</i>	(Optional) A comma-separated list of language codes. Each value in the list must be an all-lowercase RFC1766 code. If <i>languages</i> is not specified, or is empty, all languages in the database are exported. Each language is exported to a separate file using the conventions described for the <i>file</i> argument.
<i>flag</i>	(Optional) If provided, the <code>s</code> flag (system) indicates that system message dictionaries are to be exported in addition to application message dictionaries. Otherwise, only application message dictionaries are exported.

4.3 Deleting Messages

To delete messages use the following command:

```
Set status = ##class(%MessageDictionary).Delete(languages,flag)
```

languages is an optional comma-separated list of languages. If *languages* is not specified, all languages are deleted. The default value is to delete application messages only. The `s` flag (system) is an optional flag indicating whether to also delete system messages. The message names associated with include files are always deleted, but not the include files. The `d` flag (display) is also supported.

4.4 Listing Messages

To get the list of all languages that have messages loaded for a specified domain, use the **GetLanguages()** method:

```
Set list = ##class(%MessageDictionary).GetLanguages(domain,flag)
```

GetLanguages() returns a %ListofDateTypes format list of language codes in the standard [RFC1766](#) format and all in lowercase. If *domain* is specified, then only languages that exist for the specified domain are included in the list. Otherwise, all languages are included in the list. The *s* flag (system) is an optional flag indicating whether languages supported by system or application messages are to be returned. The default value is to return the languages for application messages. The *d* flag (display) is also supported.
